

A Switching Planner for Combined Task and Observation Planning

anonymous

Abstract

From an automated planning perspective the problem of practical mobile robot control in realistic environments poses many important and contrary challenges. On the one hand, the planning process must be lightweight, robust, and timely. Over the lifetime of the robot it must always respond quickly with new plans that accommodate exogenous events, changing objectives, and the underlying unpredictability of the environment. On the other hand, in order to promote efficient behaviours the planning process must perform computationally expensive reasoning about contingencies and possible revisions of subjective beliefs according to quantitatively modelled uncertainty in acting and sensing. Towards addressing these challenges, we develop a *continual planning* approach that *switches* between using a fast satisficing “classical” planner, to decide on the overall strategy, and decision-theoretic planning to solve small abstract subproblems where deeper consideration of the sensing model is both practical, and can significantly impact overall performance. We evaluate our approach in large problems from a realistic robot exploration domain.

Introduction

A number of recent integrated robotic systems incorporate a high-level *continual planning* and execution monitoring subsystem (Wyatt et al. 2010; Talamadupula et al. 2010; Kraft et al. 2008). For the purpose of planning, sensing is modelled deterministically, and beliefs about the underlying state are modelled qualitatively. Both Talamadupula et al. and Wyatt et al. identify continual planning with probabilistic models of noisy sensing and state as an important challenge for future research. Motivating that sentiment, planning according to accurate stochastic models should yield more efficient and robust deliberations. In essence, the challenge is to develop a planner that exhibits speed and scalability similar to planners employed in existing robotic systems—e.g., Wyatt et al. use a satisficing *classical* procedure—and which is also able to synthesise relatively efficient deliberations according to detailed probabilistic models of the environment.

This paper describes a *switching* domain independent planning approach we have developed to address this challenge. Our Planner is *continual* in the usual sense that plans are adapted and rebuilt online in reaction to changes

to the model of the underlying problem and/or domain—e.g., when goals are modified, or when the topological map is altered by a door being closed. It is integrated on a mobile robot platform that continuously deliberates in a stochastic dynamic environment in order to achieve goals set by the user, and acquire knowledge about its surroundings. Our planner takes problem and domain descriptions expressed in a novel extension of PPDDL (Younes et al. 2005), called *Decision-Theoretic DTPDDL*, for modelling stochastic decision problems that feature partial observability. In this paper we restrict our attention to problem models that correspond to deterministic-action multi-goal-oriented POMDPs in which all actions have non-zero cost—i.e., an optimal policy can be formatted as a finite horizon contingent plan. Moreover, we target problems of a size and complexity that is challenging to state-of-the-art sequential satisficing planners, and which are too large to be solved directly by decision-theoretic (DT) systems.

Our planner *switches*, in the sense that the base planning procedure changes depending on our robot’s subjective degrees of belief, and on progress in plan execution. When the underlying planner is a fast (satisficing) *classical* planner, we say planning is in a *sequential* session, and otherwise it is in a DT session. A *sequential* session plans, and then pursues a high-level strategy—e.g., go to the kitchen bench, and then observe the cornflakes on it. A DT session proceeds in a practically sized *abstract* process, determined according to the current sequential strategy and underlying belief-state.

We evaluate our approach in simulation on problems posed by object search and room categorisation tasks that our indoor robot undertakes. Those feature a deterministic task planning aspect with an active sensing problem. The larger of these problems features 6 rooms, 25 topological places, and 21 active sensing actions. The corresponding decision process has a number of states exceeding 10^{36} , and high-quality plans require very long planning horizons. Although our approach is not optimal, particularly as it relies on the results of satisficing sequential planning directly, we find that it does nevertheless perform better than a purely sequential replanning baseline. Moreover, it is fast enough to be used for real-time decision making on a mobile robot.

Planning Language and Notations

We give an overview of the declarative first-order language DTPDDL, an extension of PPDDL that can express probabilistic models of the sensing consequences of acting, to quantitatively capture unreliability in perception. There are straightforward compilations from problems expressed in DTPDDL to flat (and factored) representations of the underlying decision process. Although similar to Bryce’s POND input language, DTPDDL distinguishes itself by explicitly treating state and perceptual symbols separately, and by providing distinct declarations for operators (i.e., state model) and senses (i.e., observation model). In this last respect, DTPDDL admits more compact domain descriptions where sensing effects are common across multiple operators. In detail, DTPDDL has perceptual analogues of fluent and predicate symbols. For example, a simple *object search* domain would have:

```
(:functions
  (is-in ?v - visual-object) - location )
(:perceptual-functions
  (o-is-in ?v - visual-object) - location )
Where the first fluent symbol models the actual location of
objects, and the second the instantaneous sensing of ob-
jects following application of an action with sensing con-
sequences. To model sensing capabilities, we have operator-
like “sense” declarations, with preconditions expressed us-
ing state and action symbols, and uniformly positive ef-
fects over perceptual symbols. For example, where look-
for-object is the operator that applies an object detection al-
gorithm at a specific place, an object search task will have:
(:sense vision :parameters
  (?r -robot ?v -visual-object ?l -location)
:execution (look-for-object ?r ?v ?l)
:precondition (and (= (is-in ?r) ?l) )
:effect (and
  (when (= (is-in ?v) ?l)
    (probabilistic .8 (= (o-is-in ?v) ?l)))
  (when (not (= (is-in ?v) ?l))
    (probabilistic .1 (= (o-is-in ?v) ?l))))
I.e., there is a 10% false positive rate, and 20% probability of
a false negative. This representation allows us to represent
actions that have multiple independent observational effects.
```

We now review the DTPDDL syntax for describing an initial state distribution, taken verbatim from PPDDL, in order to aid us in discussing our planner. That distribution is expressed in a tree-like structure of terms. Each term is either: (1) atomic, e.g., a state proposition such as $(= (is-in \text{box}) \text{office})$, (2) probabilistic, e.g., $(\text{probabilistic } \rho_1(T_1) \dots \rho_n(T_n))$ where T_i are conjunctive, or (3) a conjunct over probabilistic and atomic terms. The root term is always conjunctive, and the leaves are atomic. For example, a simplified object search could have:¹

```
(:init (= (is-in R2D2) kitchen)
  (probabilistic .8 (= (is-in box) office)
    .2 (= (is-in box) kitchen))
  (probabilistic .3 (= (is-in cup) office))
```

¹In PPDDL, $(:init T_1 \dots T_n)$ expresses the conjunctive root of the tree – i.e., the root node $(and T_1 \dots T_n)$. Also, we shall write p , rather than $(and p)$, for conjunctive terms that contain a single atomic subterm.

.7 (= (is-in cup) kitchen)))

The interpretation is given by a *visitation* of terms: An atom is *visited* iff its conjunctive parent is visited, and a conjunctive term is visited iff all its immediate subterms are visited. A probabilistic term is visited iff its conjunctive parent is visited, and exactly one of its subterms, T_i , is visited. Each visitation of the root term according to this recursive definition defines a starting state, along with the probability that it occurs. The former corresponds to the union of all visited atoms, and the latter corresponds to the product of ρ_i entries on the visited subterms of probabilistic elements. Making this concrete, the above example yields the following flat distribution:

Probability	(is-in R2D2)	(is-in box)	(is-in cup)
.24	kitchen	office	office
.06	kitchen	kitchen	office
.56	kitchen	office	kitchen
.14	kitchen	kitchen	kitchen

Switching Continual Planner

We now describe our *switching* planning system that operates according to the continual planning paradigm given a description of the current problem and domain in DTPDDL. The system *switches* in the sense that planning proceeds in interleaved sessions in which the base planner is either *sequential/linear* or *decision-theoretic*. The system begins in a sequential session during which it runs a cost-based satisficing planner which trades off action costs, goal rewards and determinacy. This planner generates a reward-giving sequence of ground actions from the DTPDDL domain which may also include *assumptions*: actions that assume the truth of some fact that is unknown at plan time (e.g. that a box of cornflakes is located on the corner bench in the kitchen). We call this sequence a *trace*. Execution of the trace proceeds by applying the actions until the probability of the next action being applicable falls below some threshold (here 95%), at which point the planner switches to a DT session.

Because online DT planning is impractical for the size of problem we are interested in, when a DT session begins we use the trace from the preceding sequential session to restrict the state space. The state space is characterised by a limited number of propositions, chosen due to their *relevance* to the action whose scheduled execution triggered the switch to the DT session. To allow the DT planner to determine the truth of the assumptions in the trace, we add *disconfirm* and *confirm* actions to the problem for each of them. These actions yield a relatively small reward/penalty if the corresponding judgement is true/false. If a judgement action is scheduled for execution the DT session is terminated, and control is returned to a sequential session.

Whatever the session type, our continual planner maintains a factored representation of successive belief-states. As an internal representation of the $(:init)$ declaration, we keep a tree-shaped Bayesian network which gets updated whenever an action is performed, or an observation received. That belief-state representation is used: (1) as the source of candidate determinisations for sequential planning, (2) in determining when to switch to a DT session, and (3) as a mechanism to guide construction of an abstract process for

DT sessions.

Sequential Sessions

As we only consider deterministic-action POMDPs, all state uncertainty is expressed in the `(:init)` declaration. This declaration is used by our approach to define the starting state for sequential sessions, and the set of state-assumptions available to sequential planning. Writing `#` if the value of a proposition is unspecified, taking the `(:init)` example from the previous section, we have the following assumptions:

Probability	(is-in R2D2)	(is-in box)	(is-in cup)
.7	kitchen	#	kitchen
.3	kitchen	#	office
.8	kitchen	office	#
.2	kitchen	kitchen	#
1.0	kitchen	#	#

Each assumption corresponds to one distinct *relaxed* visitation of the root term. Here, a conjunctive term is visited iff its atomic subterms are visited, and zero or one of its immediate probabilistic subterms are visited. For a sequential session, the starting state corresponds to an assumption (usually unique) with probability 1.² In our example, that starting state is:

$$s_0 \equiv \{ (= (\text{is-in R2D2}) \text{kitchen}), \\ (= (\text{is-in box}) \#), (= (\text{is-in cup}) \#) \}.$$

To represent state assumptions we augment the problem posed during a sequential session with an *assumptive action* $\mathcal{A}^\circ(\rho_i; T_i)$ for each element $\rho_i(T_i)$, of each probabilistic term from `(:init)`. Here, $\mathcal{A}^\circ(\rho_i; T_i)$ can be executed if no $\mathcal{A}^\circ(\rho_j; T_j)$, $j \neq i$, has been executed from the same probabilistic term, and, either `(probabilistic .. $\rho_i(T_i)$..)` is in the root conjunct, or it occurs in T_k for some executed $\mathcal{A}^\circ(\rho_k; T_k)$. We also add constraints that forbid scheduling of assumptions about facts after actions with preconditions or effects that mention those facts. For example, the robot cannot assume it is plugged into a power source immediately after it unplugs itself. Executing $\mathcal{A}^\circ(\rho_i; T_i)$ in a state s effects a transition to a successor state s^{T_i} with probability ρ_i , and s^\perp with probability $1 - \rho_i$. Here, s^{T_i} is the union of s with atomic terms from T_i . State s^\perp is an added sink.

We now describe the optimisation criteria used during sequential sessions. Let ρ_i be the probability that the i^{th} sequenced action, a_i , from a trace of state-action pairs $\langle s_0, a_0, s_1, a_1, \dots, s_N \rangle$ does not transition to s^\perp , and $R(s_i, a_i)$ be the instantaneous reward received for executing action a_i in state s_i . The optimal trace has value:

$$V^* = \max_N \max_{s_0, a_0, \dots, s_N} \prod_{i=1..N-1} \rho_i \sum_{i=1..N-1} R(s_i, a_i),$$

DT Sessions

When an action is scheduled whose outcome is uncertain according to the underlying belief-state, the planner switches to a DT session. That plans for *small* abstract processes

²Without a loss of generality, we assume conjunctive terms list atoms that are true with probability 1 according to a visitation, and that actions do not have negative preconditions.

defined according to the action that triggered the DT session, the assumptive actions in the proceeding trace, and the current belief-state. Targeted sensing is encouraged by augmenting the reward model to reflect a heuristic value of knowing the truth about assumptions. In detail, all rewards from the underlying problem are retained. Additionally, for each relevant assumptive action $\mathcal{A}^\circ(\rho_i; T_i)$ in the current trace, we have a *disconfirm action* $\mathcal{A}^\bullet(\rho_i; T_i)$ so that for all states s :

$$R(s, \mathcal{A}^\bullet(\rho_i; T_i)) = \begin{cases} \$(T_i) & \text{if } T_i \not\subseteq s \\ \hat{\$(T_i)} & \text{otherwise} \end{cases}$$

where $\$(T_i)$ (resp. $\hat{\$(T_i)}$) is a small positive (negative) numeric quantity which captures the utility the agent receives for correctly (incorrectly) rejecting an assumption. In terms of action physics, a disconfirm action can only be executed once, and otherwise is modelled as a self-transformation. We only consider *relevant* assumptions when constructing the abstract model. If \tilde{a} is the action that switched the system to a DT session, then an assumption $\mathcal{A}^\circ(\rho_i; T_i)$ is *relevant* if it is necessary for the outcome of \tilde{a} to be determined. Continuing our simplified example, if the trace is:

$$\begin{aligned} &\mathcal{A}^\circ(.8; (= (\text{is-in box}) \text{office})); \\ &\mathcal{A}^\circ(.3; (= (\text{is-in cup}) \text{kitchen})); \\ &(\text{look box office}); (\text{look cup kitchen}); \\ &(\text{report box office}); (\text{report cup kitchen}) \end{aligned}$$

Taking the switching action \tilde{a} to be `(look box office)`, we have that $\mathcal{A}^\circ(.3; (= (\text{is-in cup}) \text{kitchen}))$ is not relevant for this session, and therefore we exclude the corresponding disconfirm action from the abstract decision process.

Given \tilde{a} , we also include another once-only self-transition action $\mathcal{A}.\text{pre}(\tilde{a})$, a *confirmation action* with the reward property:

$$R(s, \mathcal{A}.\text{pre}(\tilde{a})) = \begin{cases} \$(\text{pre}(\tilde{a})) & \text{if } \text{pre}(\tilde{a}) \subseteq s \\ \hat{\$(\text{pre}(\tilde{a}))} & \text{otherwise} \end{cases}$$

Execution of either a disconfirmation or the confirmation action returns control to a sequential session, which then continues from the underlying belief-state.

Turning to the detail of (dis-)confirmation rewards, in our integrated system these are sourced from a motivational subsystem. In this paper, for $\mathcal{A}^\bullet(\rho_i; T_i)$ actions we set $\$(x)$ to be a small positive constant, and have $\hat{\$(x)} = -\$(x)(1 - \rho)/\rho$ where ρ is the probability that x is true. For $\mathcal{A}.\text{pre}(\tilde{a})$ actions we have $\hat{\$(x)} = -\$(x)\rho/(1 - \rho)$.

In order to guarantee fast DT sessions, planning occurs for a small abstract problem. In our setting, where the underlying decision process has a deterministic action model, a significant cause of problem largeness is due to the number of states that occur with non-zero probability in the underlying belief-state. In posing a small abstract process for a DT session, we construct an abstract belief-state that is chiefly characterised by facts related to the current trace. In that abstraction, instances of operator or sense declarations whose specification mentions an excluded fact are not available. In detail, we first construct an `(:init)` declaration which contains the root term, and relevant assumptions from the

trace—e.g., (Fig. 1a) gives an example fragment, where diamonds are probabilistic terms, and circles are atomic and/or conjunctive. For each excluded atom, we compute the *entropy* of the *relevant* assumptions, *conditional* on that atom. Intuitively, lower entropy indicates an atom gives better information about assumptions. Facts are iteratively added to the belief-state in increasing order according to that measure until the belief space size reaches a predefined limit (Fig. 1b).

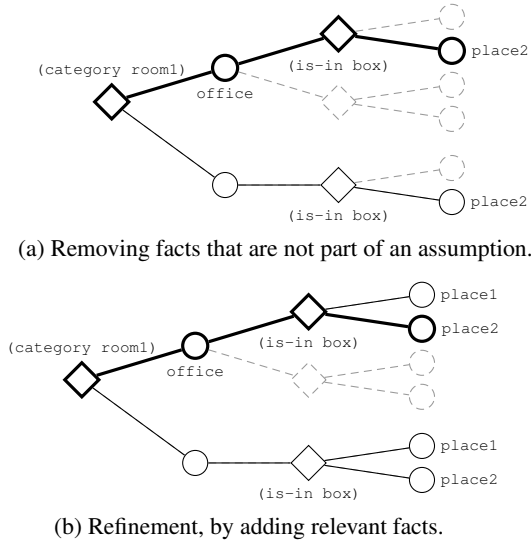

Figure 1: Abstract belief-state, and refinement.

Evaluation

We have implemented our switching approach in the MAP-SIM environment (Brenner and Nebel 2009), using DLIBM-L (King 2009) for belief revision. Sequential sessions use a modified version of Fast Downward (Helmert 2006), and DT sessions use our own contingent procedure. Since most of the problems we consider are much larger than any available DT planner can solve directly, for comparison purposes we also implemented a simple dual-mode replanning baseline approach. Here, when a switching action is scheduled for execution the DT session applies a single entropy reduction action, whose execution can provide evidence regarding the truth value of a relevant assumption. Control is then immediately returned to a new sequential session.

We evaluate our approaches in robot exploration tasks from home and office environments. Spatially, these consist of *rooms* (office/kitchen/etc), and an underlying topological map over smaller areas of space, called *places*, and connectivity between those. The mobile *robot* and *visual objects* inhabit the topological places. Objects indicate the category of space they inhabit—e.g., spoons are likely to be in kitchens. By examining view cones at places for particular objects, the robot is able to: (1) categorise space at high (room) and low (place) levels, and (2) find objects for the user, exploiting information about object co-occurrence and room categories for efficiency. Also, in the presence of a person, the robot can ask about the category of the current

room.

We compare switching to the baseline in several realistic tasks, with the number of rooms ranging from 3 (12-places, 16-objects, $|\text{states}| > 10^{21}$) to 6 (26-places, 21-objects, $|\text{states}| > 10^{36}$). We also compare those systems with near optimal policies computed using Smith’s ZMDP for small 2 room problems (4-places, 3-objects, $|\text{states}| \simeq 5000$). Our evaluation considers 3 levels of reliability in sensing: *reliable* sensors have a .1 probability of a false negative, *semi-reliable* have a chance of 0.3 of false negative and 0.1 of false positive, and *noisy* sensors with probabilities of 0.5 and 0.2 respectively. Each object class is assigned one sensor model—e.g. cornflakes may be harder to detect than refrigerators. We performed several experiments with different levels of reliability for sensing the target object(s), while keeping sensing models for non-target objects constant.

Our evaluation examines DT sessions with initial belief-states admitting between 20 and 100 abstract states with non-zero probability. We run 50 simulations in each configuration, and have a timeout on each simulation of 30 minutes (1800 seconds)³. The continual planning times are reported in Figure 2, and the quality data in Figure 3. For each task, the goal is to find one or more objects and report their position to a user. Usually there is a non-zero probability that no plan exists, as the desired object might not be present in the environment. In these experiments we only allocate reward on the achievement of all goals, therefore we find it intuitive to report average plan costs and the success rates in problems that admit a complete solution (i.e., positive reward scaled by a constant factor). The exception occurs for items f and g of Figure 3, where we report expected discounted rewards (not plan costs).

We find that if sensing is reliable, then little is gained using DT sessions, as the greedy approach of the baseline is sufficient. As sensing degrades DT sessions prove more useful. Here, time spent on DT planning increases steeply as the abstraction becomes more refined, which is compensated for by fewer planning sessions overall. More detailed abstractions lead to a better overall success rate, particularly for tasks *d* and *e*. Speaking to the effectiveness of our entropy heuristic for abstraction refinement, we see relatively high success rates irrespective of the level of refinement. Comparing finally to the best ZMDP policy, although producing relatively costly plans, the continual planners performed quite well, especially in terms success rate. A key source of inefficiency here, is due to sequential sessions always being optimistic, and refusing to abandon the search.

Related Work

Addressing task and observation planning specifically, there have been a number of recent developments where the underlying problem is modelled as a POMDP. For vision algorithm selection, Sridharan, Wyatt, and Dearden (2010) exploit an explicitly modelled hierarchical decomposition of the underlying POMDP. Doshi and Roy (2008) represent a

³All experiments were conducted on a 2.66GHz Intel Xeon X5355 using one CPU core.

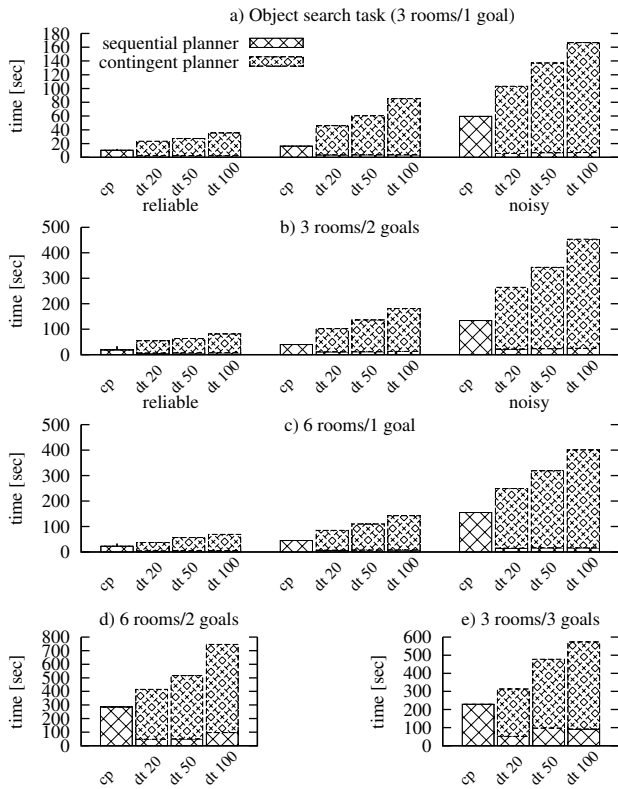

Figure 2: Average runtime

preference elicitation problem as a POMDP and take advantage of symmetry in the belief-space to exponentially shrink the state-space. Although we have been actively exploring the Doshi and Roy approach, those exploitable symmetries are not present in problems we consider due to the task planning requirement. Also, our approach is in a similar vein to *dual-mode* control (Cassandra, Kaelbling, and Kurien 1996), where planning switches between entropy and utility focuses.

There has also been much recent work on scaling offline approximate POMDP solution procedures to medium-sized instances. Recent contributions propose more efficient belief-point sampling schemes (Kurniawati et al. 2010; Shani, Brafman, and Shimony 2008), and factored representations with procedures that can efficiently exploit structures in those representations (Brunskill and Russell 2010; Shani et al. 2008). Offline domain independent systems scale to *logistics* problems with 2^{22} states (Shani et al. 2008), taking over an hour to converge, and around 10 seconds on average to perform each Bellman backup. Brunskill and Russell are able to solve problems with approximately 10^{30} states, by further exploiting certain problem features – E.g., problems where no actions have negative effects. Moving somewhat towards supporting real-time decision making, recent online POMDP solution procedures have been developed which leverage highly approximate value functions—computed using an offline procedure—and heuristics in forward search (Ross et al. 2008). These approaches are

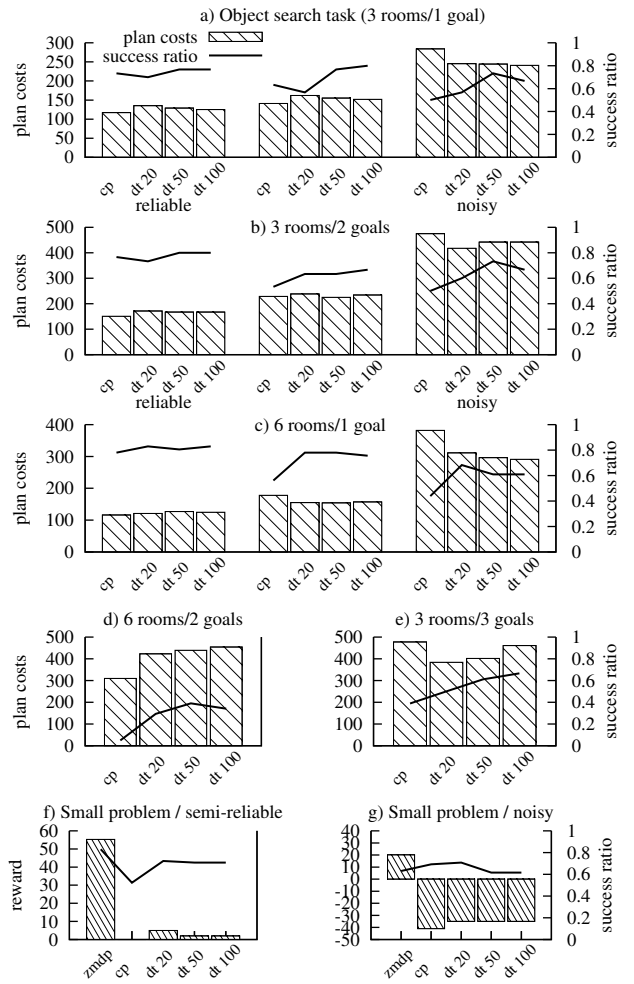

Figure 3: Average plan costs and number of successful runs.

applicable in relatively small problems, and can require expensive *problem-specific* offline processing in order to yield good behaviours. A very recent and promising online approach for larger POMDPs employs Monte-Carlo sampling to break the curse of dimensionality in situations where goal reachability is *easily* determined (Silver and Veness 2010). Our approach can also be thought of as an online POMDP solver that uses a sequential plan to guide the search, rather than (e.g., Monte-Carlo) sampling. Also, compared to most online POMDP procedures, which replan at each step, our approach involves relatively little replanning.

In the direction of leveraging *classical* systems/approaches for planning under uncertainty, the most highlighted system to date has been FFR_a (Yoon, Fern, and Givan 2007); The winning entry from the probabilistic track of the 2004 International Planning Competition. In the continual paradigm, FFR_a uses FF to compute sequential plans and execution traces. More computationally expensive approaches in this vein combine sampling strategies on valuations over *runtime variables* with deterministic planning procedures (Yoon et al. 2008).

Also leveraging deterministic planners in problems that

feature uncertainty, CONFORMANT-FF (Hoffmann and Brafman 2006) and T_0 (Palacios and Geffner 2009) demonstrate how conformant planning —i.e., sequential planning in unobservable worlds— can be modelled as a deterministic problem, and therefore solved using sequential systems. In this conformant setting, advances have been towards compact representations of beliefs amenable to existing best-first search planning procedures, and lazy evaluations of beliefs. We consider it an appealing future direction to pursue conformant reasoning during the sequential sessions we proposed. Most recently this research thread has been extended to contingent planning in fully observable non-deterministic environments (Albore, Palacios, and Geffner 2009).

Concluding Remarks

We have addressed a key challenge, specifically that of high-level continual planning for efficient deliberations according to rich probabilistic models afforded by recent integrated robotic systems. We developed a system that can plan quickly given large realistic probabilistic models, by switching between: (a) fast sequential planning, and (b) expensive DT planning in small abstractions of the problem at hand. Sequential and DT planning is interleaved, the former identifying a rewarding sequential plan for the underlying process, and the latter solving small sensing problems posed during sequential plan execution. We have evaluated our system in large real-world task and observation planning problems, finding that it performs quickly and relatively efficiently.
